Abstract

Jellium correction on the fissionability parameter is estimated within a Liquid Drop Model of the charged metallic cluster. This correction modifies the critical condition of fission and, it becomes relevant for small multicharged clusters.

PACS numbers: 36.40.Qv, 36.40.-c

Adapting the Liquid Drop Model (*LDM*) from nuclear physics to the description of finite systems (metallic clusters) [1, 2] or even infinite ones (metals) [3, 4] is straight-forward. The physical insight of the model is explained in the following way [5] : In a system with positive surface tension and positive curvature energy, the energy minimizes when the system has an environment that is as bulklike as possible, i.e., when the surface is as small in area and as concave as it can be for a given volume. Thus, the total energy of an extended system of volume V and surface area S can be readily expressed as a sum of volume, surface, electrostatic (for charged systems) and curvature terms.

Despite the errors arising from the shell structure of finite systems, *LDM* can be successfully used in understanding the fission of multiply charged metallic clusters [6]. Neglecting the curvature energy (with supposition on

a small curvature of the droplet), the total energy of the charged droplet is assumed to be comprised of three terms in this approach,

$$E_T = E_b + E_S + E_C. \quad (1)$$

The leading term of (1) may be written $E_b = \varepsilon \cdot N$, where N is the number of constituent particles and ε is the energy per particle in the limit $\frac{V}{S} \rightarrow \infty$. When a spherical droplet of radius R_o is deformed (conserving the volume) toward an ellipsoidal shape its area changes to

$$S \approx 4\pi R_o^2 \left(1 + \frac{2}{5}\beta^2\right), \quad (2)$$

upon the second-order approximation in powers of the deformation parameter β .

The surface energy, E_s , in this the simplest deformation of the droplet is therefore

$$E_S \approx 4\pi\sigma R_o^2 \left(1 + \frac{2}{5}\beta^2\right), \quad (3)$$

where σ is the surface tension. Also, in the simplest manner, when the deformed droplet electrified to a charge q , it has an electrostatic (Coulomb) energy

$$E_C \approx \alpha \frac{q^2}{4\pi\epsilon R_o} \left(1 - \frac{1}{5}\beta^2\right). \quad (4)$$

Here, $\alpha = \frac{3}{5}$ for a uniform distribution of charge q inside the droplet or $\alpha = \frac{1}{2}$ when the charge q is spread over the surface only. Looking at eqs. (3 - 4) one can observe that the relative strengths of the Coulomb and surface forces will determine the stability of the spherical shape and hence its tendency to fission.

The Coulomb energy of a charged metallic cluster is a long - standing controversial problem in cluster physics. Thus, the dimensionless coefficient α (see eq. 4) takes experimental values around 0.4 [7] while from the classical electrostatic reasons, two different theoretical results for this coefficient have been derived: $\alpha = \frac{1}{2}$ from the spherical- capacitor approach [8], and $\alpha = \frac{3}{8}$ from the image-potential approach [9]. Recently, Seidl and Perdew [10] have established that, classically, $\alpha = \frac{1}{2}$ by either approach and the experimental deviation from this value must be accounted for by quantum effects. Their theoretical result is derived in a "point-charge-plus-continuum" model for

jellium within which the excess electric charge is uniformly distributed in a surface shell between the radii $(R_o^3 - r_s^3)^{\frac{1}{3}}$ and R_o . In this model, $\alpha = \frac{1}{2}$ is a correct result in the limit $z \cdot \frac{r_s^3}{R_o^3} \ll 1$ which means large clusters and not so many electric charges ($z \cdot e$). Actually, according with the above model, α is larger than $\frac{1}{2}$ depending on the charge $z \cdot e$ and the number of the constituent particles. This follows from the fact that, increasing the cluster charge or decreasing the number of the cluster constituents, the volume of the charged surface shell increases relative to that of all the cluster volume and, consequently, $\alpha \rightarrow \frac{3}{5}$ which is the right value for uniformly charged sphere. This assumption can be relevant for small multicharged clusters. With these in mind somewhat corrections on the critical condition of cluster fission within a *Liquid Drop Model (LDM)* are necessary. This is, briefly, the aim for that the present paper is addressed.

In the "Wigner - crystal" model of jellium, the positive charge of the ions is replaced by a rigid uniform positive background with the charge density $+e\bar{n} = e\frac{3}{4\pi r_s^3}$ inside the sphere of radius R_o . The valence electrons are point charges sitting at equilibrium position inside the sphere of radius R_o . Sometimes, by various reasons, the cluster ionization, the above model is replaced by the "point - charge - plus - continuum" model of jellium. In this approach, the electrons to be removed remain point charges while, the other electrons are replaced by a continuous, mobile fluid of negative charge. This system achieves equilibrium when the net electric field vanishes wherever the density of continuum negative charge does not. In this way, when the point electrons are still located inside the droplet, the density of continuum negative charge must neutralize the positive background everywhere but, inside the spheres of radius r_s around the point electrons the density of continuum negative charge must vanish. As the electrons are pulled out through the surface of the cluster their "classical holes" deform, remaining behind inside the surface while conserving its volume, after the electrons have been removed to $x = \infty$, these "classical holes" are spread over a shell of charge density $+e\bar{n}$ between the radii R_o and $R = (R_o^3 - zr_s^3)^{\frac{1}{3}}$, where z is the number of the electrons which have been removed. In this way, the Coulomb potential, subject of the Laplace equation both inside the neutral part of the cluster ($0 < r < R$) and outside the cluster ($r > R_o$) and of the Poisson equation in the cluster

region between R_o and R , reads

$$\Phi(r) = \begin{cases} A, & \text{if } r < R; \\ -\frac{e\bar{n}}{6\epsilon}r^2 - \frac{B}{r} + C, & \text{if } R < r < R_o; \\ -\frac{B}{r}, & \text{if } r > R_o. \end{cases} \quad (5)$$

Imposing appropriate boundary conditions, the A,B,C and D constants are readily determined and, the electrostatic potential in the charged shell ($R < r < R_o$) is

$$\Phi_{shell} = -\frac{e\bar{n}}{6\epsilon}r^2 - \frac{R^3}{3\epsilon r}e\bar{n} + \frac{e\bar{n}}{6\epsilon R_o} \left(R_o^3 + 2R^3 \right) - \frac{e\bar{n}}{3\epsilon_o R_o} \left(R^3 - R_o^3 \right), \quad (6)$$

where ϵ_o is the electric permittivity of free space. Under the assumption that $\epsilon = \epsilon_o$, the electrostatic self-energy reads

$$\begin{aligned} W &= \frac{1}{2} \int dV e\bar{n} \cdot \Phi_{shell} \\ &= \frac{1}{2} \cdot \frac{(e)^2}{4\pi\epsilon R_o} \cdot \frac{3}{5 \frac{r_s^6}{R_o^6}} \cdot \left(2 - 5 \left(1 - z \frac{r_s^3}{R_o^3} \right) + 3 \left(1 - z \frac{r_s^3}{R_o^3} \right)^{\frac{5}{3}} \right). \end{aligned} \quad (7)$$

As we can see, for $z = 1$, the above amount is the electrostatic self-energy obtained by Seidl and Perdew (equation 3 in [10]). Further, we will note $\frac{r_s^3}{R_o^3}$ by η and, in the second-order approximation in powers of this parameter, the above equation becomes

$$W = \frac{(ze)^2}{4\pi\epsilon R_o} \cdot \frac{1}{2} \left(1 + \frac{\eta}{9} + \frac{\eta^2}{27} + \dots \right), \quad (8)$$

which means that the value of the α parameter having corrections from the jellium approach of the metallic cluster reads

$$\alpha = \frac{1}{2} \left(1 + \frac{\eta}{9} + \frac{\eta^2}{27} + \dots \right) \quad (9)$$

and, it is easy to see that when $\eta \rightarrow 0$ (the charged shell tends to an infinitesimal thin layer) then $\alpha \rightarrow \frac{1}{2}$ and, when $\eta \rightarrow 1$ (the charged surface shell has an increasing trend by various reasons: small clusters and/or multicharged

clusters) then $\alpha \rightarrow \frac{3}{5}$. On the other hand, the radius of the spherical cluster can be expressed as $R_o = r_s N^{\frac{1}{3}}$ which means that $\eta = \frac{z}{N}$ and α becomes

$$\alpha = \frac{1}{2} \left(1 + \frac{z}{9N} + \frac{z^2}{27N^2} + \dots \right), \quad (10)$$

which shows that the dimensionless parameter α is larger than $\frac{1}{2}$ depending on the charge z and the number of cluster constituents N .

As we have said, the above correction on the value of the dimensionless parameter α may have somewhat relevance on the critical condition of cluster fission within the *LDM*.

For a droplet N^{z+} , where N is the number of atoms and z is the charge in units e , the surface energy is proportional to $N^{\frac{2}{3}}$ and is a minimum when the droplet is spherical. The surface energy disfavors deformation (see eq. 3). On the other hand, the Coulomb energy depends on $N^{-\frac{1}{3}}$ and is a maximum when the droplet is undeformed (see eq. 4); it favors the deformation. The relative strengths of the Coulomb and surface forces will determine the stability of the shape and hence its tendency to fission. Looking at equations (3 - 4) and, taking into account the last equation for the α , one can say that the droplet is unstable to (classical) spontaneous decay, even at zero temperature, when

$$\begin{aligned} \frac{z^2}{N} \left(1 + \frac{z}{9N} + \frac{z^2}{27N^2} + \dots \right) &\rightarrow \left(\frac{z^2}{N} \left(1 + \frac{z}{9N} + \frac{z^2}{27N^2} + \dots \right) \right)_c \\ &= \frac{64\pi^2 \epsilon r_s^3 \sigma}{e^2}. \end{aligned} \quad (11)$$

Looking at the above equations we may say that the corresponding critical size, N_c , for α given by (10) slightly differs from that corresponding to $\alpha = \frac{1}{2}$. The jellium correction rises the lower bound of the critical sizes.

With high enough excitation, fission is always an allowed decay channel. Whether fission is observed or not, however, depends on where the threshold energy for competing reactions lies in relation to the fission threshold. Evaporation is the main competitor in both nuclear and cluster fission. Looking, again, at the above equations one may see that it is expected a slight decreasing of the fission barrier for α given by (10) relatively to that for $\alpha = \frac{1}{2}$.

As a concluding remark, one may say that the above jellium correction on the fissionability criterion within a *LDM*, apart from the fact that promotes

a correct (natural) way to account for the Coulomb energy as a part in the fission condition, this rises (indeed not very much) the lower bound of the critical sizes as a consequence of α increasing and, on the other hand, decreases the fission barrier by the same considerations.

The author thanks to Professor M. Apostol for many useful discussions.
